Project Description

This project will focus on the backend portion of our system development project since we were already planning to use PHP to do so. Our client is a reception hall in Rivière-des-Prairies, and the way they book and schedule events for clients is all done in person. This can be rather repetitive and time-consuming, so we are planning to develop a system where the booking process can all be done online without the need to go in person.

This web application will be used by the 2 owners and clients. The clients can book an event without the need to log in and plan it via a virtual contract. This can contain information such as the date, number of people, menu, etc., at the customer's event. Once completed, it gets sent off to the owners via email. The owners (admin), on the other hand, have access to a secure back-end interface where they can do all the necessary CRUD operations, such as viewing, updating events and then also deleting them once their event has passed.

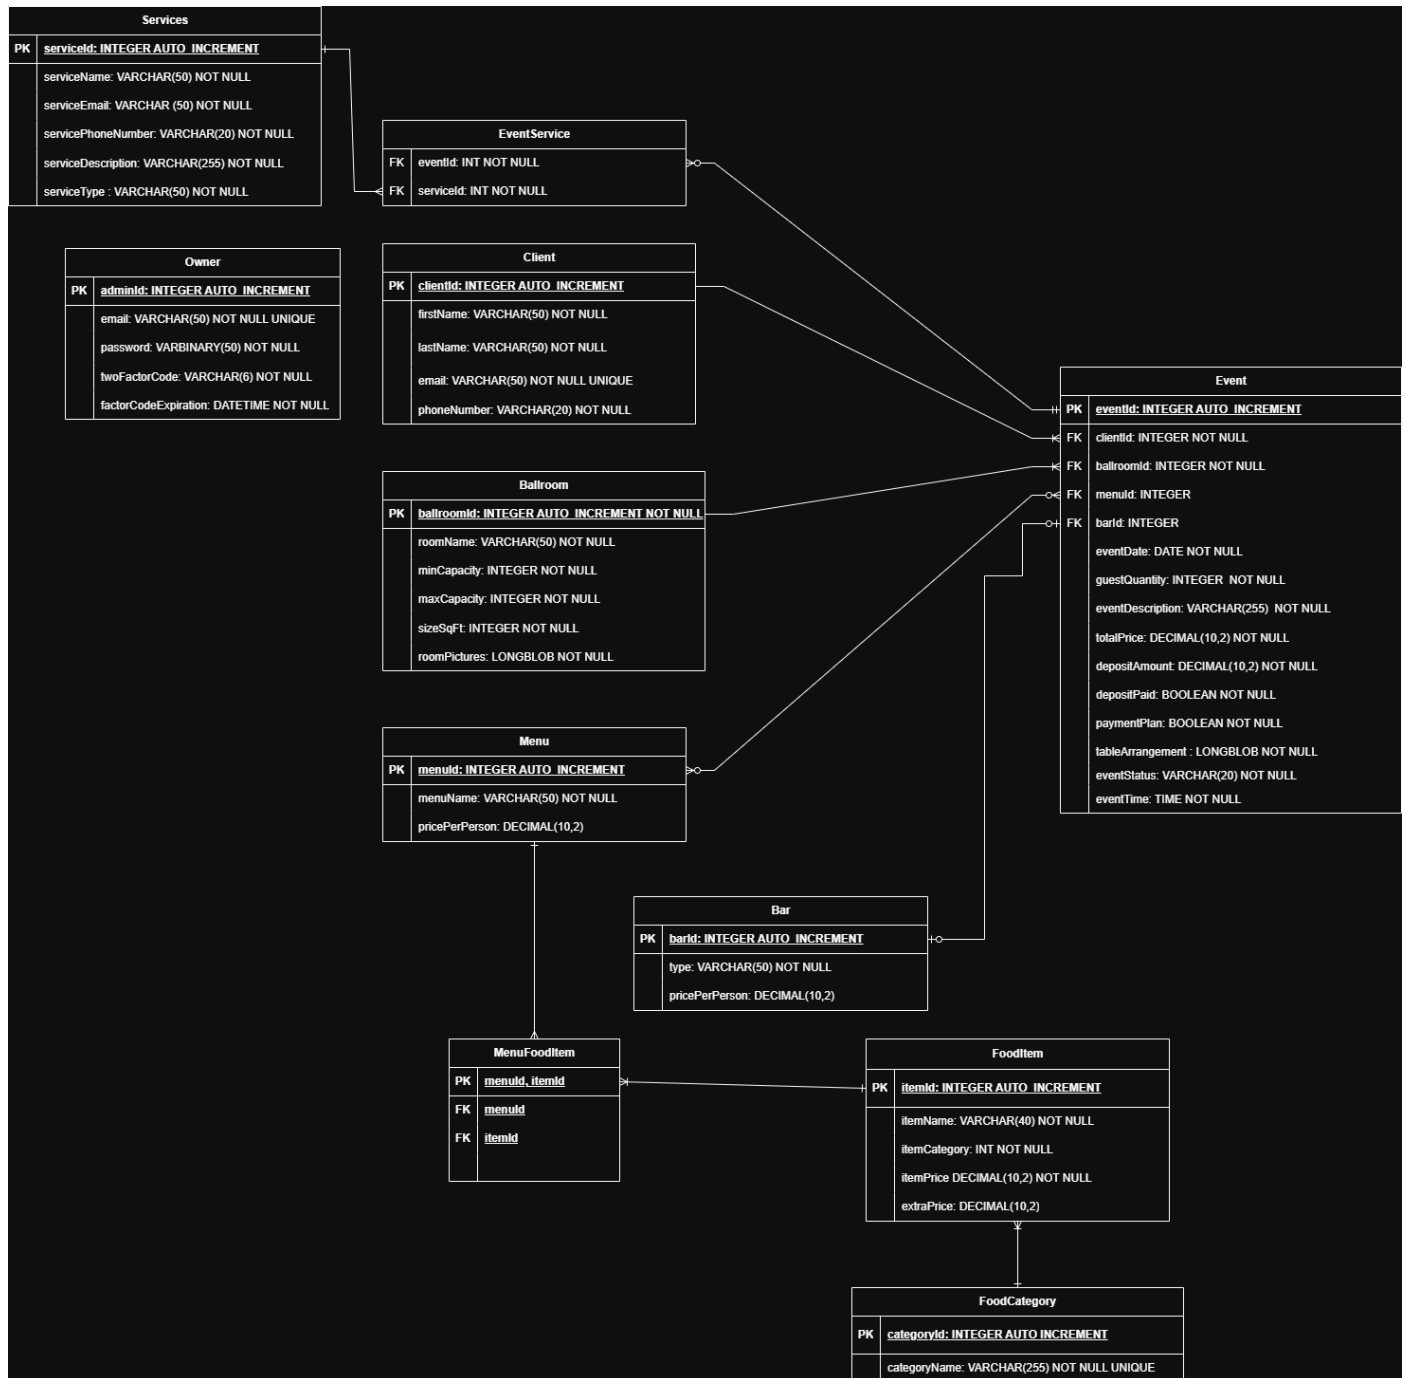

As mentioned before, we will use PHP for the backend part of this project, and it will have many important core features. We will include 2FA for admins and a structured booking workflow with centralized client management. By digitizing the reservation process, this system aims to reduce repetitive manual tasks, improve organization, and provide a more efficient and accessible experience for both clients and business owners.

We will manage version control through a Github repository to manage the codebase and the many changes it will go through: <https://github.com/DPerrotta06/System-Dev-Project.git>

Feature Suite

Feature	Description
Admin login	Log in with 2-factor authentication
Client management	Add, view, search, edit, and delete clients
Event calendar	Weekly and monthly views
Booking form	Clients can submit event requests online
Menu management	Link food items to name menu packages
Service tracking	Attach multiple third-party services to a single event

ERD

Deployment Plan

For testing purposes and during the stages of development, we will use Wampoon's Apache web server and mySql as a database management system. Once the project is ready for the production phase, we will ask our clients if we can deploy the application on their website via their cloud server. This would allow us to easily integrate our application into their current website and use it within their own environment. If they refuse, the application can be deployed on a domain that one of our team members will purchase, where the domain name and server space will be configured specifically for this project.

The deployment workflow will work by pushing the finalized codebase to a Github repository and then transferring it to the server that is hosting our project. Connection to the server will be connected and secured through PHP along with an imported database schema; specific configurations will be adjusted according to the hosting environment's properties. This flow allows a smooth adaptation from development to a completely functional web application for our clients to use.
